Generating effective referring expressions using charts

Nikos Engonopoulos and Alexander Koller
University of Potsdam, Germany
{engonopo|akoller}@uni-potsdam.de

Abstract
We present a novel approach for generating effective referring expressions (REs). We define a synchronous grammar formalism that relates surface strings with the sets of objects they describe through an abstract syntactic structure. The grammars may choose to require or not that REs are distinguishing. We then show how to compute a chart that represents, in finite space, the complete (possibly infinite) set of valid REs for a target object. Finally, we propose a probability model that predicts how the listener will understand the RE, and show how to compute the most effective RE according to this model from the chart.

1 Introduction
The fundamental challenge in the generation of referring expressions (REG) is to compute an RE which is effective, i.e. understood as intended by the listener. Throughout the history of REG, we have approximated this as the problem of generating distinguishing REs, i.e. REs that are only satisfied by a unique individual in the domain. This has been an eminently successful approach, as documented e.g. in the overview article of Krahmer and van Deemter (2012) and a variety of recent shared tasks involving RE generation (Gatt and Belz, 2010; Belz et al., 2008; Koller et al., 2010).

Nonetheless, reducing effectiveness to uniqueness is limiting in several ways. First, in complex, real-world scenes it may not be feasible to generate fully distinguishing REs, or these may have to be exceedingly complicated. It is also not necessary to generate distinguishing REs in such situations, because listeners are very capable of taking the discourse and task context into account to resolve even ambiguous REs. Conversely, listeners can misunderstand even a distinguishing RE, so uniqueness is no guarantee for success. We propose instead to define and train a probabilistic RE resolution model $P(a|t)$, which directly captures the probability that the listener will resolve a given RE $t$ to some object $a$ in the domain. An RE $t$ will then be "good enough" if $P(a^*|t)$ is very high for the intended target referent $a^*$.

Second, in an interactive setting like the GIVE Challenge (Koller et al., 2010), the listener may behave in a way that offers further information on how they resolved the generated RE. Engonopoulos et al. (2013) showed how an initial estimate of the distribution $P(a|t)$ can be continuously updated based on the listener’s behavior, and that this can improve a system's ability to detect misunderstandings. It seems hard to achieve this in a principled way without an explicit model of $P(a|t)$.

In this paper, we present an algorithm that generates the RE $t$ that maximizes $P(a^*|t)$, i.e. the RE that has the highest chance to be understood correctly by the listener according to the probabilistic RE resolution model. This is a challenging problem, since the algorithm must identify that RE from a potentially infinite set of valid alternatives. We achieve this by using a chart-based algorithm, a standard approach in parsing and realization, which has (to our knowledge) never been used in REG.

We start by defining a synchronous grammar formalism that relates surface strings to their interpretations as sets of objects in a given domain (Section 3). This formalism integrates REG with surface realization, and allows us to specify in the grammar whether REs are required to be distinguishing. We then show how to compute a chart for a given grammar and target referent in Section 4. Section 5 defines a log-linear model for $P(a|t)$, and presents a Viterbi-style algorithm for computing the RE $t$ from the chart that maximizes $P(a^*|t)$. Section 6 concludes by discussing how to apply our algorithm to the state-of-the-art approaches of Krahmer et al. (2003) and Golland et al. (2010), and how to address a particular challenge involving cycles that arises when dealing
with probabilistic listener models.

2 Related Work

RE generation is the task of generating a natural-language expression that identifies an object to the listener. Since the beginnings of modern REG (Appelt, 1985; Dale and Reiter, 1995), this problem has been approximated as generating a distinguishing description, i.e. one which fits only one object in the domain and not any of the others. This perspective has made it possible to apply search-based (Kelleher and Kruijff, 2006), logic-based (Areeces et al., 2008) and graph-based (Krahmer et al., 2003) methods to the problem, and overall has been one of the success stories of NLG.

However, in practice, human speakers frequently overspecify, i.e. they include information in an RE beyond what is necessary to make it distinguishing (Wardlow Lane and Ferreira, 2008; Koolen et al., 2011). An NLG system, too, might include redundant information in an RE to make it easier to understand for the user. Conversely, an RE that is produced by a human can often be easily resolved by the listener even if it is ambiguous. Here we present an NLG system that directly uses a probabilistic model of RE resolution, and is capable of generating ambiguous REs if it predicts that the listener will understand them.

Most existing REG algorithms focus on generating distinguishing REs, and then select the one that is best according to some criterion, e.g. most human-like (Krahmer et al., 2003; FitzGerald et al., 2013) or most likely to be understood (Garoufi and Koller, 2013). By contrast, Mitchell et al. (2013) describe a stochastic algorithm that computes human-like, non-relational REs that may not be distinguishing. Golland et al. (2010) are close to our proposal in spirit, in that they use a log-linear probability model of RE resolution to compute a possibly non-distinguishing RE. However, they use a trivial REG algorithm which is limited to grammars that only permit a (small) finite set of REs for each referent. This is in contrast to general REG, where there is typically an infinite set of valid REs, especially when relational REs (“the button to the left of the plant”) are permitted.

Engonopoulos et al. (2013) describe how to update an estimate for $P(a | t)$ based on a log-linear model based on observations of the listener’s behavior. They use a shallow model based on a string $t$ and not an RE derived from a grammar, and they do not discuss how to generate the best $t$. The algorithm we develop here fills this gap.

Our formalism for REG can be seen as a synchronous grammar formalism; it simultaneously derives strings and their interpretations, connecting the two by an abstract syntactic representation. This allows performing REG and surface realization with a single algorithm, along the lines of SPUD (Stone et al., 2003) and its planning-based implementation, CRISP (Koller and Stone, 2007). Probabilistic synchronous grammars are widely used in statistical machine translation (Chiang, 2007; Graehl et al., 2008; Jones et al., 2012) and semantic parsing (Zettlemoyer and Collins, 2005; Wong and Mooney, 2007). Lu and Ng (2011) have applied such grammars to surface realization. Konstas and Lapata (2012) use related techniques for content selection and surface realization (with simple, non-recursive grammars).

Charts are standard tools for representing a large space of possible linguistic analyses compactly. Next to their use in parsing, they have also been applied to surface realization (Kay, 1996; Carroll et al., 1999; Kaplan and Wedekind, 2000). To our knowledge, ours is the first work using charts for REG. This is challenging because the input to REG is much less structured than in parsing or realization.

3 Grammars for RE generation

We define a new grammar formalism that we use for REG, which we call semantically interpreted grammar (SIG). SIG is a synchronous grammar formalism that relates natural language strings with the sets of objects in a given domain which they describe. It uses regular tree grammars (RTGs) to describe languages of derivation trees, which then project to strings and sets.

3.1 Derivation trees

We describe the abstract syntax of an RE by its derivation tree, which is a tree over some ranked signature $\Sigma$ of symbols representing lexicon entries and grammatical constructions. A (ranked) signature is a finite set of symbols $r \in \Sigma$, each of which is assigned an arity $ar(r) \in \mathbb{N}_0$. A tree over the signature $\Sigma$ is a term $t(r_1, \ldots, r_n)$, where $r \in \Sigma$, $n = ar(r)$, and $t_1, \ldots, t_n$ are trees over $\Sigma$. We write $T_\Sigma$ for the set of all trees over $\Sigma$.

Fig. 1b shows an example derivation tree for the RE “the square button” over the signature $\Sigma = \{\text{def}|1, \text{square}|1, \text{button}|0\}$, where $r|n$ indicates that the symbol $r$ has arity $n$. In term nota-
(a) \( \{b_2\} \leftarrow \mathcal{I}_M \) \hspace{1cm} (b) \( \mathcal{I}_S \) \hspace{1cm} (c) \( \text{"the square button"} \)

Figure 1: A SIG derivation tree (b) with its interpretations (a, c).

**String interpretation.** We interpret derivation trees simultaneously as strings and sets. First, let \( \Delta \) be a finite alphabet, and let \( \Delta^* \) be the string algebra over \( \Delta \). We define a string interpretation over \( \Delta \) as a function \( \mathcal{I}_S \) that maps each \( r|_n \in \Sigma \) to a function \( \mathcal{I}_S(r) : (\Delta^*)^n \rightarrow \Delta^* \). For instance, we can assign string interpretations to our example signature \( \Sigma \) as follows; we write \( w_1 \bullet w_2 \) for the concatenation of the strings \( w_1 \) and \( w_2 \).

\[
\begin{align*}
\mathcal{I}_S(\text{def})(&w_1) = \text{the } \bullet w_1 \\
\mathcal{I}_S(\text{square})(w_1) = \text{square } \bullet w_1 \\
\mathcal{I}_S(\text{button}) = \text{button}
\end{align*}
\]

Since the arity of \( \mathcal{I}_S(r) \) is the same as the arity of \( r \) for any \( r \in \Sigma \), we can use \( \mathcal{I}_S \) to recursively map derivation trees to strings. Starting at the leaves, we map the tree \( r(t_1, \ldots, t_n) \) to the string \( \mathcal{I}_S(r) \mathcal{I}_S(t_1) \cdots \mathcal{I}_S(t_n) \), where \( \mathcal{I}_S(t_i) \) is the string that results from recursively applying \( \mathcal{I}_S \) to the subtree \( t_i \). In the example, the subtree \( \text{button} \) is mapped to the string “button”. We then get the string for the subtree \( \text{square(button)} \) by concatenating this with “square”, obtaining the string “square button” and so on, as shown in Fig. 1c.

**Relational interpretation.** We further define a relational interpretation \( \mathcal{I}_R \), which maps each \( r|_n \in \Sigma \) to a function \( \mathcal{I}_R(r) : R(U)^n \rightarrow R(U) \), where \( R(U) \) is a class of relations. We define \( \mathcal{I}_R \) over some first-order model structure \( M = (U, L) \), where \( U \) is a finite universe \( U \) of individuals and \( L \) interprets a finite set of predicate symbols as relations over \( U \). We let \( R(U) \) be the set of all \( k \)-place relations over \( U \) for all \( k \geq 0 \). The subsets of \( U \) are the special case of \( k = 1 \). We write \( k(R) \) for the arity of a relation \( R \in R(U) \).

For the purposes of this paper, we construct \( \mathcal{I}_R \) by combining the following operations:

- The denotations of the atomic predicate symbols of \( M \); see Fig. 2 for an example.

\[ U = \{b_1, b_2, b_3\} \quad \text{button} = \{b_1, b_2, b_3\} \]
\[ \text{round} = \{b_1, b_3\} \quad \text{square} = \{b_2\} \]
\[ \text{left_of} = \{(b_1, b_2), (b_2, b_3)\} \]
\[ \text{right_of} = \{(b_2, b_1), (b_3, b_2)\} \]

Figure 2: A simple model, illustrated as a graph.

- \( \text{proj}_i(R) = \{a_i \mid \langle a_i, \ldots, a_{k(R)} \rangle \in R\} \) is the projection to the \( i \)-th component; if \( i > k(R) \), it evaluates to \( \emptyset \).
- \( R_1 \cap_i R_2 = \{\langle a_1, \ldots, a_{k(R_1)} \rangle \in R_1 \mid a_i \in R_2\} \) is the intersection on the \( i \)-th component of \( R_1 \); if \( i > k(R_1) \), it evaluates to \( \emptyset \).
- For any \( a \in U \), \( \text{uniq}_i(R) \) evaluates to \( \{a\} \) if \( R = \{a\} \), and to \( \emptyset \) otherwise.
- For any \( a \in U \), \( \text{member}_a(R) \) evaluates to \( \{a\} \) if \( a \in R \), and to \( \emptyset \) otherwise.

For the example, we assume that we want to generate REs over the scene shown in Fig. 2; it consists of the universe \( U = \{b_1, b_2, b_3\} \) and interprets the atomic predicate symbols button, square, round, left_of, and right_of. Given this, we can assign a relational interpretation to the derivation tree in Fig. 1b using the following mappings:

\[
\begin{align*}
\mathcal{I}_R(\text{def})(R_1) &= R_1 \\
\mathcal{I}_R(\text{square})(R_1) &= \text{square } \cap_1 R_1 \\
\mathcal{I}_R(\text{button}) &= \text{button}
\end{align*}
\]

We evaluate a derivation tree to a relation as we did for strings (cf. Fig. 1a). The subtree \( \text{button} \) maps to the denotation of the symbol button, i.e. \( \{b_1, b_2, b_3\} \). The subtree \( \text{square(button)} \) evaluates to the intersection of this set with the set of square individuals, i.e. \( \{b_2\} \); this is also the relational interpretation of the entire derivation tree. We thus see that “the square button” is an RE that describes the individual \( b_2 \) uniquely.

3.2 Semantically interpreted grammars

Now we define grammars that describe relations between strings and relations over \( U \). We achieve this by combining a regular tree grammar (RTG, (Gécseg and Steinby, 1997; Comon et al., 2007)), describing a language of derivation trees, with a string interpretation and a relational interpretation. An RTG \( G = (N, \Sigma, S, P) \) consists of a finite set \( N \) of nonterminal symbols, a ranked signature \( \Sigma \), a start symbol \( S \in N \), and a finite set \( P \) of production rules \( A \rightarrow r(B_1, \ldots, B_n) \), where
A, B₁, . . . , Bₙ ∈ N and r|n ∈ Σ. We say that
a tree t₂ ∈ TΣ can be derived in one step from
t₁ ∈ TΣ, t₁ ⇒ t₂, if it can be obtained by replac-
ing an occurrence of B in t₁ with t and P con-
tains the rule B → t. A tree tₙ ∈ TΣ can be
derived from t₁, t₁ ⇒ * tₙ, if there is a sequence
t₁ ⇒ . . . ⇒ tₙ of length n ≥ 0. For any nontermi-
al A, we write Lₐ(G) for the set of trees t ∈ TΣ
with A ⇒ * t. We simply write L(G) for LΣ(G)
and call it the language of G.

We define a semantically interpreted grammar
(SIG) as a triple G = (G, IS, IR) of an RTG G
over some signature Σ, together with a string inter-
pretation IS over some alphabet Δ and a relational
interpretation IR over some universe U, both of
which interpret the symbols in Σ. We assume that
every terminal symbol r ∈ Σ occurs in at most
one rule, and that the nonterminals of G are pairs
Aₓ of a syntactic category A and a semantic index
b = iₓ(Aₓ). A semantic index indicates the indi-
cidual in U to which a given constituent is meant
to refer to, see e.g. (Kay, 1996; Stone et al., 2003).
Note that SIGs can be seen as specific Interpreted
Regular Tree Grammars (Koller and Kuhlmann,
2011) with a set and a string interpretation.

We ignore the start symbol of G. Instead, we
say that given some individual b ∈ U and syntactic
category A, the set of referring expressions for b is
REᵥ(A, b) = \{ t ∈ Lₓ(A)(G) | IR(t) = \{ b \} \}, i.e.
we define an RE as a derivation tree that G can
derive from Aₓ and whose relational interpretation
is \{ b \}. From t, we can read off the string IS(t).¹

3.3 An example grammar

Consider the SIG G in Fig. 3 for example. The
grammar is written in template form. Each rule
is instantiated for all semantic indices specified
in the line above; e.g. the symbol round denotes
the set \{ b₁, b₃ \}, therefore there are rules N₁ →
round₁(N₁) and N₃ → round₃(N₃). The values
of IR and IS for each symbol are specified
below the RTG rule for that symbol.

We can use G to generate NPs that refer to the
target referent b₂ given the model shown in Fig. 2
by finding trees in LNPb₂(G) that refer to \{ b₂ \}.
One such tree is t₁ = def₁₂(square₁₂(button₁₂)),
a more detailed version of the tree in Fig. 1b.
It can be derived by NPb₂ ⇒ def₁₂(N₁₂) ⇒
def₁₂(square₁₂(N₁₂)) ⇒ t₁. Because IS(t₁) =
\{ b₂ \}, we see that t₁ ∈ REᵥ(NP, b₂); it represents

¹Below, we will often write the RE as a string when
the derivation tree is clear.
4.1 RE generation charts

Generally speaking, a chart is a packed data structure which describes how larger syntactic representations can be recursively built from smaller ones. In applications such as parsing and surface realization, the creation of a chart is driven by the idea that we consume some input (words or semantic atoms) as we build up larger structures. The parallel to this intuition in REG is that “larger” chart entries are more precise descriptions of the target, which is a weaker constraint than input consumption. Nonetheless, we can define REG charts whose entries are packed representations for large sets of possible REs, and compute them in terms of these entries instead of RE sets.

Technically, we represent charts as RTGs over an extended set of nonterminals. A chart for generating an RE of syntactic category A for an individual \( b \in U \) is an RTG \( C = (N', \Sigma, S', P') \), where \( N' \subseteq N \times R(U) \) and \( S' = A_0 / \{ b \} \). Intuitively, the nonterminal \( A_0 / \{ a_1, \ldots, a_n \} \) expresses that we intend to generate an RE for \( b \) from \( A \), but each RE that we can derive from the nonterminal actually denotes the referent set \( \{ a_1, \ldots, a_n \} \).

A chart for the grammar in Fig. 3 is shown in Fig. 4. To generate an NP for \( b_2 \), we let its start symbol be \( S' = NP_{b_2} / \{ b_2 \} \). The rule \( NP_{b_2} / \{ b_1, b_2, b_3 \} \rightarrow button_{b_2} \) says that we can generate an RE \( t \) with \( I_R(t) = \{ b_2 \} \) from the nonterminal symbol \( NP_{b_2} \) by expanding this symbol with the grammar rule \( NP_{b_2} \rightarrow button_{b_2} \).

\[
A \rightarrow r(B_1, \ldots, B_n) \quad \text{in} \quad G
\]
\[
B'_i = B_i / R_1, \ldots, B'_n = B_n / R_n \quad \text{in} \quad N'
\]
\[
\text{Add rule } A' \rightarrow r(B'_1, \ldots, B'_n) \quad \text{to } P'
\]

Figure 5: The chart computation algorithm.

Given a SIG \( G \), a syntactic category \( A \), and a target referent \( b \), we can compute a chart \( C \) for \( RE_G(A, b) \) using the parsing schema in Fig. 5. The schema assumes that we have a rule \( A \rightarrow r(B_1, \ldots, B_n) \) in \( G \); in addition, for each \( 1 \leq i \leq n \) it assumes that we have already added the nonterminal \( B'_i = B_i / R_i \) to the chart, indicating that there is a tree \( t_i \) with \( B_i \Rightarrow^* t_i \) and \( I_R(t_i) = R_i \). Then we know that \( t = r(t_1, \ldots, t_n) \) can be derived from \( A \) and that \( R' = I_R(t) \). We can therefore add the nonterminal \( A' = A / R' \) and the production rule \( A' \rightarrow r(B'_1, \ldots, B'_n) \) to the chart; this rule can be used as the first step in a derivation of \( t \) from \( A \). We can optimize the algorithm by adding \( A' \) and the rule only if \( R' \neq \emptyset \).

The algorithm terminates when it can add no more rules to the chart. Because \( U \) is finite, this always happens after a finite number of steps, even if there is an infinite set of REs. For instance, the chart in Fig. 4 describes an infinite language of REs, including “the square button”, “the button to the left of the round button”, “the button to the left of the button to the right of the square button”, etc.

Thus it represents relational REs that are nested arbitrarily deeply through a finite number of rules.

After termination, the chart contains all rules by which a nonterminal can be decomposed into other (productive) nonterminals. As a result, \( L(C) \) contains exactly the REs for \( b \) of category \( A \):

**Theorem 1** If \( C \) is a chart for the SIG \( G \), the syntactic category \( A \), and the target referent \( b \), then \( L(C) = RE_G(A, b) \).

5 Computing best referring expressions

The chart algorithm allows us to compactly represent all REs for the target referent. We now show how to compute the best RE from the chart.

We present a novel probability model \( P(b/t) \) for RE resolution, and take the “best” RE to be the
Figure 6: The derivation tree for “the button to the left of the square button”.

one with the highest chance to be understood as intended. Next to the best RE itself, the algorithm also computes the entire distribution $P(b|t)$, to support later updates in an interactive setting.

Nothing in our algorithm hinges on this particular model; it can also be used with any other scoring model that satisfies a certain monotonicity condition which we spell out in Section 5.2.

5.1 A log-linear model for effective REs

We model the probability $P(b|t)$ that the listener will resolve the RE $t$ to the object $b$ using a log-linear model with a set of feature functions $f(a, t, M)$, where $a$ is an object, $t$ is a derivation tree, and $M$ is the relational interpretation model.

We focus on features that only look at information that is local to a specific subtree of the RE, such as the label at the root. For instance, a feature $f_{\text{round}}(a, t', M)$ might return 1 if the root label of $t'$ is round and $a$ is round in $M$, and 0 otherwise. Another feature $f_{\text{def}}(a, t', M)$ might return 1/k if $t'$ is of the form $\text{def}_b(t''')$, $R = R_0(t'')$ has $k$ elements, and $a \in R$; and 0 otherwise. This feature counterbalances the ability of the grammar in Fig. 3 to say “the $w$” even when $w$ is a non-unique description by penalizing descriptions with many possible referents through lower feature values.

When generating a relational RE, the derivation tree naturally splits into separate regions, each of which is meant to identify a specific object. These regions are distinguished by the semantic indices in the nonterminals that derive them; e.g., in Fig. 6, the subtree for “the square button” is an attempt to refer to $b_2$, whereas the RE as a whole is meant to refer to $b_1$. To find out how effective the RE is as a description of $b_1$, we evaluate the features at all nodes in the region top$(t)$ containing the root of $t$.

Each feature function $f_i$ is associated with a weight $w_i$. We obtain a score tuple $\text{sc}(t')$ for some subtree $t'$ of an RE as follows:

$$\text{sc}(t') = \langle s(a_1, t', M), \ldots, s(a_m, t', M) \rangle,$$

where $U = \{a_1, \ldots, a_m\}$ and $s(a, t', M) = \sum_{i=1}^{m} w_i \cdot f_i(a, t', M)$. We then combine these into a score tuple $\text{score}(t) = \sum_{u \in \text{top}(t)} \text{sc}(t,u)$ for the whole RE $t$, where $t, u$ is the subtree of $t$ below the node $u$. Finally, given a score tuple $s = \langle s_1, \ldots, s_m \rangle$ for $t$, we define the usual log-linear probability distribution as

$$P(a_i|t) = \text{prob}(a_i, s) = \frac{e^{s_i}}{\sum_{j=1}^{m} e^{s_j}}.$$

The best RE for the target referent $b$ is then

$$\text{best}_G(A, b) = \arg \max_{t \in \text{RE}_G(A,b)} \text{prob}(b, \text{sc}(t)).$$

For illustration, we consider a number of REs for $b_1$ in our running example. We use $f_{\text{round}}$ and $f_{\text{def}}$ and let $w_{\text{round}} = w_{\text{def}} = 1$. In this case, the RE “the button” has a score tuple $\langle 1/3, 1/3, 1/3 \rangle$, which is the sum of the tuple $\langle 0, 0, 0 \rangle$ for $f_{\text{round}}$ (since the RE does not use the “round” rule) and the tuple $\langle 1/3, 1/3, 1/3 \rangle$ for $f_{\text{def}}$ (since “button” is three-way ambiguous in $M$). This yields a uniform probability distribution over $U$ (see Fig. 7). By contrast, “the round button” gets $\langle 3/2, 0, 3/2 \rangle$, resulting in the distribution in the second line of Fig. 7. This RE is judged better than “the button” because it assigns a higher probability to $b_1$.

Relational REs involve derivation trees with multiple regions, only the top one of which is directly counted for $P(b|t)$ (see Fig. 6). We incorporate the quality of the other regions through appropriate features. In the example, we use a feature $f_{\text{leftof}}(a, t', M) = \sum_{b: (a,b) \in \text{leftof}} P(b|t'')$, where $t''$ is the second subtree of $t'$. This feature computes the probability that the referent to which the listener resolves $t''$ is actually to the right of $a$, and will thus take a high value if $t''$ is a good RE for $b_2$. Assuming a probability distribution of $P(b_2|t') = 0.78$ and $P(b_1|t') = P(b_3|t') = 0.11$ for $t' =$ “the square button”, we get the tuple $\langle 0.78, 0.11, 0 \rangle$ for $f_{\text{leftof}}$, yielding the third line of Fig. 7 for $w_{\text{leftof}} = 1$.

5.2 Computing the best RE

We compute bestG(A, b) from the chart by adapting the Viterbi algorithm. Our key data structure assigns a score tuple is(A′) to each nonterminal A′ in the chart. Intuitively, if the semantic index of A′ is b, then is(A′) is the score tuple sc(t) for the tree t ∈ L_A(C) which maximizes P(b|t). We also record this best tree as bt(A′). Thus the algorithm is correct if, after running it, we obtain bestG(A, b) = bt(A_b/{b}).

As is standard in chart algorithms, we limit our attention to features whose values can be computed bottom-up by local operations. Specifically, we assume that if A′ → r(B′_1, . . . , B′_n) is a rule in the chart and t_i is the best RE for B′_i for all i, then the best RE for A′ that can be built using this rule is r(t_1, . . . , t_n). This means that features must be monotonic, i.e., that the RE that seemed locally best for B′_i leads to the best RE overall.

Under this assumption, we can compute is(A′) and bt(A′) bottom-up as shown in Fig. 8. We iterate over all nonterminals A′ in the chart in a fixed linear order, which we call the evaluation order. Then we compute is(A′) and bt(A′) by maximizing over the rules for A′. Assume that the best RE for A′ can be constructed using the rule A′ → r(B′_1, . . . , B′_n). Then if, at the time we evaluate A′, we have fully evaluated all the B′_i in the sense that bt(B′_i) is actually the best RE for B′_i, the algorithm will assign the best RE for A′ to bt(A′), and its score tuple to is(A′). Thus, if we call an evaluation order exact if the nonterminals on the right-hand side of each rule in the chart come before the nonterminal on the left-hand side, we can inductively prove the following theorem:

**Theorem 2** If the evaluation order is exact, then for every nonterminal A′ in the chart, we obtain bt(A′) = arg max_{t ∈ L_A′(C)} P(ix(A′)|t) and is(A′) = sc(bt(A′)).

In other words, the algorithm is correct if the evaluation order is exact. If it is not, we might compute a sub-optimal RE as bt(A′), which underestimates is(A′). The choice of evaluation order is thus crucial.

6 Evaluating charts with cycles

It remains to show how we can determine an exact evaluation order for a given chart. One way to think about the problem is to consider the ordering graph O(C) of the chart C (see Fig. 9 for an example). This is a directed graph whose nodes are the nonterminals of the chart; for each rule A′ → r(B′_1, . . . , B′_n) in C, it has an edge from B′_i to A′ for each i. If this graph is acyclic, we can simply compute a topological sort of O(C) to bring the nodes into a linear order in which each B′_i precedes A′. This is enough to evaluate charts using certain simpler models. For instance, we can apply our REG algorithm to the log-linear model of Golland et al. (2010). Because they only generate REs with a bounded number of relations, their grammars effectively only describe finite languages. In such a case, our charts are always acyclic, and therefore a topological sort of O(C) yields an exact evaluation order.

This simple approach will not work with grammars that allow arbitrary recursion, as they can lead to charts with cycles (indicating an infinite set of valid REs). E.g., the chart in Fig. 4 contains a rule N_b/⟨b⟩ → square_b/N_b/⟨{b}⟩ (shown in Fig. 9), which can be used to construct the RE t′ = “the square square button” in addition to the RE t = “the square button”. Such cycles can be increasing with respect to a log-linear probability model, i.e. the model considers t′ a better RE than t. Indeed, t has a score tuple of (0, 2, 0), giving P(b_2|t) = 0.78. By contrast, t′ has a score tuple of (0, 3, 0), thus P(b_2|t′) = 0.91. This can be continued indefinitely, with each addition of “square” increasing the probability of being resolved to b_2. Thus, there is no best RE for b_2; every RE can be improved by adding another copy of “square”.

In such a situation, it is a challenge to even compute any score for every nonterminal without running into infinite loops. We can achieve this by decomposing O(C) into its strongly connected components (SCCs), i.e. the maximal subgraphs in which each node is reachable from any other node. We then consider the component graph O′(C); its nodes are the SCCs of O(C), and it has an edge from c_1 to c_2 if O(C) has an edge from some node in c_1 to some node in c_2. O′(C) is acyclic by construction, so we can compute a topological
sort and order all nonterminals from earlier SCCs before all nonterminals from later SCCs. Within each SCC, we order the nonterminals in the order in which they were discovered by the algorithm in Fig. 5. This yields a linear order on nonterminals, which at least ensures that by the time we evaluate a nonterminal \( A' \), there is at least one rule for \( A' \) whose right-hand nonterminals have all been evaluated; so \( \text{is}(A') \) gets at least some value.

In our example, we obtain the order \( N_{b_2}/\{b_1, b_2, b_3\}, N_{b_2}/\{b_2\}, NP_{b_2}/\{b_2\} \). The rule \( N_{b_2}/\{b_2\} \rightarrow square_{b_2}(N_{b_2}/\{b_2\}) \) will thus not be considered in the evaluation of \( N_{b_2}/\{b_2\} \), and the algorithm returns the “square button”. The algorithm computes optimal REs for acyclic charts, and also for charts where all cycles are decreasing, i.e. using the rules in the cycle make the RE worse. This enables us, for instance, to encode the REG problem of Krahmer et al. (2003) into ours by using a feature that evaluates the rule for each attribute to its (negative) cost according to the Krahmer model. Krahmer et al. assume that every attribute has positive cost, and is only used if it is necessary to make the RE distinguishing. Thus all cycles in the chart are decreasing.

One limitation of the algorithm is that it does not overspecify. Suppose that we extend the example model in Fig. 2 with a color predicate \( \text{green} = \{b_2\} \). We might then want to prefer “the green square button” over “the square button” because it is easier to understand. But since all square objects (i.e. \( \{b_2\} \)) are also green, using “green” does not change the denotation of the RE, i.e. it is represented by a loop from \( N_{b_2}/\{b_2\} \) to \( N_{b_2}/\{b_2\} \), which is skipped by the algorithm. One idea could be to break such cycles by the careful use of a richer set of nonterminals in the grammar; e.g., they might record the set of all attributes that were used in the RE. Our example rule would then become \( N_{b_2}/\{b_2\}/\{square, green\} \rightarrow green_{b_2}(N_{b_2}/\{b_2\}/\{square\}) \), which the algorithm can make use of (see Fig. 10).

7 Conclusion

We have shown how to generate REs using charts. Based on an algorithm for computing a chart of all valid REs, we showed how to compute the RE that maximizes the probability of being understood as the target referent. Our algorithm integrates REG with surface realization. It generates distinguishing REs if this is specified in the grammar; otherwise, it computes the best RE without regard to uniqueness, using features that prefer unambiguous REs as part of the probability model.

Our algorithm can be applied to earlier models of REG, and in these cases is guaranteed to compute optimal REs. The probability model we introduced here is more powerful, and may not admit “best” REs. We have shown how the algorithm can still do something reasonable in such cases, but this point deserves attention in future research, especially with respect to overspecification.

We evaluated the performance of our chart algorithm on a number of randomly sampled input scenes from the GIVE Challenge, which contained 24 objects on average. Our implementation is based on the IRTG tool available at irtg.googlecode.com. While in the worst case the chart computation is exponential in the input size, in practice runtimes did not exceed 60 ms for the grammar shown in Fig. 3.

We have focused here on computing best REs given a probability model. We have left training the model and evaluating it on real-world data for future work. Because our probability model focuses on effectiveness for the listener, rather than human-likeness, our immediate next step is to train it on an interaction corpus which records the reactions of human listeners to system-generated REs. A further avenue of research is to deliberately generate succinct but ambiguous REs when the model predicts them to be easily understood. We will explore ways of achieving this by combining the effectiveness model presented here with a language model that prefers succinct REs.
